Lasers in Dentistry: Minimally Invasive Instruments for the Modern Practice

Course Author(s): Steven R. Pohlhaus, DDS  
**CE Credits:** 4 hours  
**Intended Audience:** Dentists, Dental Hygienists, Dental Students, Dental Hygiene Students  
**Date Course Online:** 06/11/2012  
**Last Revision Date:** 10/19/2018  
**Course Expiration Date:** 10/18/2021  
**Cost:** Free  
**Method:** Self-instructional  
**AGD Subject Code(s):** 10, 135, 250

Online Course: [www.dentalcare.com/en-us/professional-education/ce-courses/ce394](http://www.dentalcare.com/en-us/professional-education/ce-courses/ce394)

**Disclaimer:** Participants must always be aware of the hazards of using limited knowledge in integrating new techniques or procedures into their practice. Only sound evidence-based dentistry should be used in patient therapy.

**Conflict of Interest Disclosure Statement**
- The author is a laser trainer for Fotona, LLC.

**Introduction – Lasers in Dentistry**
Lasers have been used in dentistry for over 30 years. Recent developments in technology and differing wavelengths are creating a host of innovative treatments using various dental lasers. The modern practitioner needs to be familiarized with these devices and understand the possibilities and limitations of each device. Lasers in Dentistry: Minimally Invasive Instruments for the Modern Practice course will be designed to help educate the dentists and dental hygienists on lasers and clear the confusion regarding the various wavelengths available.
Course Contents

Overview

Shortly after the invention of the first ruby laser in 1960, researchers began investigating lasers potential use in dentistry. Dental lasers are now well-established in the dental armamentarium and their future potential is even greater. Recent developments in technology and differing wavelengths are creating a host of innovative treatments using various dental lasers. The modern practitioner needs to be familiarized with these devices and understand the possibilities and limitations of each device. This course is designed to help educate clinicians and to clear the confusion regarding the various wavelengths available.

Every discipline of dentistry can benefit from the use of these modern devices. There are currently five predominant types of lasers available for dental professionals: diode, Nd:YAG, Er:YAG, Er:YSGG, and CO₂.

Practitioners who want to integrate laser technology into their patient care face the daunting task of trying to sort through all the information available to make the right decision. Each device and wavelength available offers specific capabilities and limitations. A proper understanding of dental lasers potential is not possible without a basic understanding of laser physics and biological interactions.

Learning Objectives

Upon completion of this course, the dental professional should be able to:

- Understand basic laser physics.
- Describe the concept of stimulated emission and what is an active medium.
- Differentiate between the concepts of energy versus power.
- Describe the difference between average power and peak power.
- Understand the three different laser emission modes and their role in peak power and thermal effects on target tissue.
- Understand the impact of pulse duration on peak power and thermal effects on target tissue.
- Define thermal relaxation.
- State the four types of tissue interaction.
- Define chromophore.
- Know the tissue temperatures that result in hyperthermia, coagulation, denaturation, vaporization, and carbonization.
- Describe the four major categories of dental lasers in use today.
- State the three safety practices required for all laser types.
- Understand the role of laser fluorescence in caries diagnosis and management.
- Know which types of lasers are able to be used on hard tissue.
- Understand the basic principles of hard tissue ablation and laser restorative techniques.
- Describe the various soft tissue surgical techniques.
- Define PIPS and its role in endodontics.
State uses of low level laser therapy/biostimulation in dentistry.

**Glossary**

- **ablation** – The process of removing tissue with a laser through vaporization or mechanical disruption.

- **absorption** – Specific molecules in the tissue known as chromophores absorb the photons. The light energy is then converted into other forms of energy to perform work.

- **active medium** – The laser component that actually produces laser light when stimulated. Dental lasers use crystals, gas, or semiconductors as their active media.

- **beam transfer hardware** – Mirrors, optical fibers, or hollow wave guide hardware that carries the laser beam from the machine to the handpiece.

- **chromophore** – The tissue component that absorbs the laser energy and converts it into thermal energy.

- **coherence** – The tendency of laser light waves to travel with their peaks and valleys in unison.

- **continuous wave mode** – A form of laser emission when the laser is on continuously.

- **divergence** – The tendency of the laser beam to spread outward once it exits the handpiece. Divergence varies depending on the specific laser and hardware used.

- **energy density** – The amount of laser energy in an area of exposed tissue.

- **Er,Cr:YSGG** – Erbium, Chromium - doped Yttrium Scandium Gallium Garnet crystal.

- **Er:YAG** – Erbium-doped Yttrium Aluminium Garnet crystal.

- **gated wave mode** – A form of laser emission where the beam is blocked part of the time by a shutter device creating a pulsed laser emission.

- **laser** – Light Amplification by Stimulated Emission of Radiation.

- **millijoule** – Measurement of energy.

- **monochromatic** – In laser science refers specifically to the fact that lasers produce a single wavelength of light.

- **Nd:YAG** – Neodymium-doped Yttrium Aluminium Garnet crystal.

- **optical pumping** – Flash lamp stimulation of an active medium.

- **output coupler** – A semi-transparent mirror in the resonator that the laser beam passes through into the beam transfer hardware.

- **photobiomodulation** – The process whereby laser energy is used to stimulate positive clinical outcomes such as pain relief and improved healing.

- **power** – Rate of doing work, measured in Watts.

- **pulse duration** – The amount of time a laser pulse is on, measured in microseconds.

- **reflection** – When the laser beam bounces off the surface with no penetration or interaction at all.

- **resonator** – The mirrored chamber surrounding the active medium that helps to amplify the laser light produced.

- **scattering** – The tendency of laser light to bounce in multiple directions once it enters tissue.

- **stimulated emission** – The process whereby the active medium is stimulated by an external source of light or electricity to produce laser light.
**thermal relaxation** – The ability of tissue to absorb and dissipate heat produced by pulsed dental lasers.

**transmission** – When laser energy can pass through superficial tissues to interact with deeper areas.

**watt** – Power measurement of energy produced over time.

### History of Dental Lasers

In 1916 Albert Einstein wrote to a friend “A splendid light has dawned on me about the absorption and emission of radiation.” Einstein never created a laser, but at that time he theorized the concept of stimulated emission, which is the scientific basis for the creation of laser light. The first ruby laser was developed in 1960 and many other lasers were created rapidly thereafter. Dental researchers began investigating lasers' potential and Stern and Sognnaes reported in 1965 that a ruby laser could vaporize enamel. The thermal effects of continuous wave lasers at that time would damage the pulp. Other wavelengths were studied over the ensuing decades for both hard and soft tissue applications.

Practitioners and researchers began to find clinical oral soft tissue uses of medical CO₂ and Nd:YAG lasers until in 1990 when the first pulsed Nd:YAG laser designed specifically for the dental market was released. The year 1997 saw the FDA clearance of the first true dental hard tissue Er:YAG laser and the Er,Cr:YSGG a year later. Semiconductor based diode lasers emerged in the late 1990s as well. Recently a CO₂ laser was approved for use on tooth structure.

### Laser Physics

#### Stimulated Emission

The word laser is an acronym standing for “Light Amplification by Stimulated Emission of Radiation.” A laser beam is created from a substance known as an active medium, which when stimulated by light or electricity produces photons of a specific wavelength. Lasers are characteristically monochromatic, unidirectional, coherent, and emitted from a stimulated active medium. Monochromacity means that a laser beam is made of a single wavelength of light, and all dental lasers are found in the visible or infrared portion of the electromagnetic spectrum. Once a laser beam is produced it will travel in one direction (unidirectional), though the divergence of the beam varies by type of laser and the associated transmission hardware. Coherence is the property that not only is a laser a single wavelength but all the peaks and valleys of each wave travel in unison.

The active media in dentistry can be solid state, gas, or semiconductor. Solid state lasers are a crystal matrix host doped with the light emitting, excitable atoms; such as erbium laced yttrium, aluminium, and garnet (Er:YAG). CO₂ is a popular laser where the active medium is sealed in an air tight chamber. Diode lasers have a semiconductor that when stimulated with electricity, laser light is emitted.

Stimulated emission is a phenomenon that occurs within the active medium. For example, in solid state Er:YAG lasers the erbium is stimulated by light from a flashlamp with a process known as optical pumping. As an erbium atom absorbs a photon, its electrons are elevated to higher energy level. When the electrons return to a lower energy state, two identical photons are emitted and these photons can further stimulate more atoms in a chain reaction, resulting in amplification of the light produced. Mirrors surrounding the active medium called a resonator further increase this light energy. One of the mirrors called the output coupler is less than one hundred percent reflective. Light leaks from the output coupler, and these are the photons that form the laser beam. Once the beam is created it is carried to the target tissue by various types of beam transfer hardware. Mirrors in articulated arms and optical fibers are common examples of this hardware.

The laser beam is collimated and exits in the handpiece as a column of light. The beam will diverge at various rates depending on the device, the handpiece, and the tip used. Once the beam reaches the tissue it will have a specific spot size depending on the distance
Thermal and Physical Implications of Pulsed Versus Continuous Emissions

Energy is the ability to work and is measured in Joules. The measuring unit for most dental laser applications is the millijoule (mJ), and this is a parameter that is controlled by the operator.

from the handpiece and its specific divergence. The energy density refers to the actual amount of energy reaching the tissue within the spot size. This energy density varies considerably depending on the parameters of energy, divergence, and distance.

Figure 1. Stimulated Emission.

Figure 2. Diagram of the basic components of dental lasers.
Power is the rate of doing work, or energy used over a period of time and is measured in Watts (W). One Watt equals one joule per second. These are the watts displayed on the machines’ control panels. A laser beam can be emitted either as a continuous beam or in a pulsed fashion.

The pulse rate per second is measured in Hertz (Hz). The wattage displayed on the laser unit is a product of the Millijoule (energy) per pulse times the number of pulses per second (hertz). Peak Power refers to the power level in each individual laser pulse and this measurement is not visible to the operator, yet it is the most important variable dictating how the laser beam will interact with the target tissue.

Continuous wave emission mode means the laser is on the whole time it is turned on. In these lasers peak power equals the wattage output displayed. There are two basic forms of pulsed laser modes: gated wave and free running pulsed. A gated wave pulse is usually created with a shutter that blocks the laser beam from reaching the handpiece and target tissue at varying speeds. This pulse form is sometimes referred to as “chopped.” The laser is on constantly but the shutter device blocks the light from transmitting. “Superpulsed” lasers are a form of gated lasers with extremely short pulse durations. Free running pulsed lasers are not on constantly but emit photons in powerful bursts of energy measured in millionths of seconds. To better understand these concepts one can take an example of a flashlight. When a flashlight is turned on it is in continuous wave mode, moving one’s hand back and forth across the beam is gated wave mode, and turning it on and off repeatedly is free running pulsed mode. Each of these temporal emission modes has important characteristics when the laser energy interacts with tissues that need to be understood well by the practitioner. Peak power can be a difficult concept to understand but its importance cannot be overstated. Each pulse has a set amount of energy, usually the millijoules displayed on the unit. As shorter pulses are used this same energy is effectively squeezed into a smaller space, which increases the peak power of the pulse. One can think of a rubber

Figure 3. Peak power equals average power. A laser running in continuous mode has equal peak power and average power. Average power is what is displayed on the control panel. Peak power is not shown but can be calculated.
Figure 4. Average power is half of peak power. In a simple gated wave laser average power is half peak power. Here a blinking shutter blocks the laser beam half the time.

Figure 5. High peak power/low average power. Average power is a tiny fraction of peak power in free running pulsed mode. These lasers flash off and on like a strobe light in short bursts of energy from 50 to 1000 millionths of a second (microseconds). In this example a laser displaying 5 watts running at ten hertz with a fifty microsecond pulse will have peak power of 10,000 watts per pulse. This powerful burst of energy allows for efficient hard tissue cutting with minimal thermal effects.
band around a wrist as an analogy. If the rubber band is lifted three inches, it will have a fixed amount of energy in it. Now if the rubber band is slowly returned to the wrist, it will not hurt a bit. If it is let go, the energy is released in a much shorter time and it will sting and make a popping sound. Yet the actual energy expended is identical. Hard tissue dental lasers can have peak powers in the thousands of watts, and these short burst of extreme power allow for the efficient cutting of enamel, dentin and bone.

The thermal implications of the three pulse modes are profound. Thermal relaxation refers to the ability of the target tissue to absorb heat produced by laser interaction. In continuous mode there is no thermal relaxation at all and potentially damaging heat can build in the tissue quickly. Gated wave mode presents basically a half on/half off exposure to laser energy and the ability of the tissue to absorb the heat is limited. A superpulsed lasers improve on the standard gated mode's thermal effects through sophisticated pulse time control. Thermal relaxation occurs the most when free running pulsed lasers are used. Each pulse is temporally very short, anywhere from 50 to one thousand millionths of a second depending on which device and settings are used. There is adequate time between each pulse to allow the tissue to absorb and dissipate the heat to minimize thermal damage. This lack of tissue heating results in the lowered post-operative discomfort and predictable healing seen after many laser procedures. It also contributes to the ability to perform many operative dentistry procedures and even some soft tissue ones without local anesthesia. An excellent analogy is if a finger is moved rapidly through a candle flame it will not burn as the tissue can absorb and dissipate the momentary high heat exposure. If the same finger is moved slowly through the flame it will get burned eventually. Placing the finger in the flame and holding it there will cause rapid thermal damage.

**Tissue Interactions and Biological Effects**

Once a laser beam is produced it is aimed at tissue to perform a specific task. As the energy reaches the biological interface one of four interactions will occur; reflection, transmission, scattering, or absorption.

- **Absorption** – Specific molecules in the tissue known as chromophores absorb the photons. The light energy is then converted into other forms of energy to perform work.
- **Reflection** – The laser beam bounces off the surface with no penetration or interaction at all. Reflection is usually an undesired effect, but a useful example of reflection is found when Erbium lasers reflect off titanium allowing for safe trimming of gingiva around implant abutments.
- **Transmission** – The laser energy can pass through superficial tissues to interact with deeper areas. Retinal surgery is an example; the laser passes through the lens to treat the retina. The deeper penetration seen with Nd:YAG and diode lasers is an example of tissue transmission as well.
- **Scattering** – Once the laser energy enters the target tissue it will scatter in various directions. This phenomenon is usually not helpful, but can help with certain wavelengths biostimulative properties.

Absorption is the most important interaction. Each wavelength has specific chromophores that absorb their energy. This absorbed energy is converted into thermal and and/or mechanical energy that is used to perform the work desired. Near infrared lasers like diodes and Nd:YAGs are mostly absorbed by pigments such as hemoglobin and melanin. Erbium and CO₂ lasers are predominantly absorbed by water and hydroxyapatite. The shorter, near infrared wavelengths of diodes and Nd:YAG lasers also penetrate tissue more deeply than the longer, mid infrared wavelengths of the erbium and CO₂ lasers.

There are five important types of biological effects that can occur once the laser photons enter the tissue: fluorescence, photothermal, photodisruptive, photochemical, and photobiomodulation.

- **Fluorescence** happens when actively carious tooth structure is exposed to the 655nm visible wavelength of the Diagnodent diagnostic device. The amount of fluorescence is related to the size of
Figure 6. The four tissue interactions.

Figure 7. The wavelengths of the four most common dental lasers are shown where they occur in the electromagnetic spectrum. All are in the non-ionizing infrared part of the spectrum. Absorption patterns of the chromophore water, melanin, and hemoglobin are superimposed on the graph. This absorption is what converts light energy into thermal and/or mechanical energy to do work.
phagocytosis, and the like with various wavelengths. The exact mechanism of these effects is not clear but it is theorized they occur mostly through photochemical and photobiological interactions within the cellular matrix and mitochondria. Biostimulation is used dentally to reduce postoperative discomfort and to treat maladies such as recurrent herpes and aphthous stomatitis. Low Level Laser Therapy (LLLT) is another term used to describe this phenomenon.

When a dental laser is employed it can be used in contact mode or non-contact mode. The laser tip directly touches the target tissue in contact mode. In non-contact mode the laser is pointed at a distance from the target tissue anywhere from a few millimeters, such as in operative dentistry, or up to several centimeters when performing biostimulation.

When a laser heats oral tissues certain reversible or irreversible changes can occur:
- Hyperthermia – below 50 degrees C
- Coagulation and Protein Denaturation – 60+ degrees C
- Vaporization – 100+ degrees C
- Carbonization – 200+ degrees C

Irreversible effects such as denaturation and carbonization result in thermal damage that cause inflammation, pain, and edema.

**Types of Dental Lasers**

The dental lasers in common use today are Erbium, Nd:YAG, Diode, and CO₂. Each type of laser has specific biological effects and procedures associated with them. A solid understanding of each of these categories of devices is imperative for any clinician hoping to pursue laser use in their practice.

**Erbium Lasers**

Erbium lasers are built with two different crystals, the Er:YAG (yttrium aluminum garnet crystal) and Er,Cr:YSGG (chromium sensitized yttrium scandium gallium garnet crystal). They do have different wavelengths, Er:YAG has 2940 nm and Er,Cr:YSGG has 2780 nm. Though similar, there is a significant water absorption difference between these two wavelengths.
procedures which has the added benefit of root surface decontamination.  

Nd:YAG Lasers

Nd:YAG lasers were the first types of true pulsed lasers to be marketed exclusively for dental use in 1990. They are a near infrared wavelength of 1064 nm. This wavelength is absorbed by pigment in the tissue, primarily hemoglobin and melanin. Photothermal interaction predominates and the laser energy here can penetrate deeply into tissues. Contact and non-contact mode are both utilized depending on the procedure being performed. Nd:YAG also have excellent biostimulative properties. Nd:YAG lasers have the unique capacity to stimulate fibrin formation. This effect is maximized when the pulse duration is set at 650 microseconds.

These lasers are primarily used for periodontal treatments. Their proclivity for pigmented tissue allows for effective debridement and disinfection of periodontal pockets. Bacterial decontamination in tissues treated with Nd:YAG laser energy also contributes to resolution of periodontal infection. They also have the ability to stimulate fibrin formation with longer pulse duration settings and this phenomenon is utilized to biologically seal treated pockets and act as a scaffold for reattachment. The ability to form fibrin is also utilized when forming clots in extraction sites which can help prevent alveolitis and enhance osteogenesis. Nd:YAG lasers can also be used for multiple soft tissue procedures such as gingivectomy, frenectomy, impression troughing, and biopsy. The deep penetration and the near infrared wavelength of these lasers also make them ideal for photobiomodulation procedures.

Diode Lasers

Diode lasers are becoming quite popular due to their compact size and relatively affordable pricing. A specialized semiconductor that produces monochromatic light when stimulated electrically is common to all diode lasers. A simple laser pointer is an example of a diode laser. Diode lasers can be used in both contact and non-contact mode and can function with continuous wave or gated pulse
modes. They are not capable of free running pulsed mode. Diode lasers are invisible near infrared wavelengths and current machines range from 805–1064 nm. One exception is the Diagnodent caries diagnostic laser which uses a visible red wavelength of 655 nm.

Diode lasers are soft tissue only. The chromophores are pigments such as hemoglobin and melanin, similar to the Nd:YAG absorption spectrum. However, most surgical procedures with diodes are not as a result of laser photons interacting with tissue. Diode laser fibers are “initiated” by burning articulating paper onto the tip. This initiation causes the light energy to be absorbed by the burnt material on the tip, effectively making it a hot piece of quartz. The laser energy cuts indirectly by heating up the fiber optic tip. Diode lasers do not have enough peak power to efficiently cut tissue on their own without initiation. If one defines “laser dentistry” as light interacting with tissue, then diode procedures are not laser dentistry ones.

They are quite effective for a host of intraoral soft tissue procedures such as gingivectomy, biopsy, impression roughing, and frenectomy. Diode lasers also exhibit bactericidal capabilities and can be used for adjunctive periodontal procedures. They are also used for laser assisted tooth whitening. Diode lasers have excellent photobiomodulation properties as well.

**CO₂ Lasers**

CO₂ Lasers have been available in medicine since the early 1970s and have been used in dentistry for more than 25 years. They are a 10,600 nm infrared wavelength, which is highly absorbed by water. Articulated arms or hollow waveguides are used to transmit CO₂ laser beams and quartz optical fibers cannot be used. The CO₂ gas is in a chamber with nitrogen and helium and the active medium is pumped with an electrical current. CO₂ lasers are very efficient and exhibit excellent hemostasis. The traditional 10,600 nm CO₂ lasers are currently for soft tissue uses only. They are continuous wave lasers that can be operated in gated wave modes, including what are termed “superpulsed” modes. It is important to note that even the superpulsed mode is not a free running pulsed mode. These superpulsed gated modes offer improved surgical control with less charring of tissue.

CO₂ lasers are excellent tools for incising tissue for multiple purposes. Incisional and excisional biopsies, frenectomy, gingivectomy, pre prosthetic procedures, and the like are all achieved with excellent hemostasis. Sutures are rarely needed and the controlled thermal effects and sealing of nerve endings often makes for a very comfortable post-operative experience for the patient. This wavelength is also very effective for ablation and vaporization of leukoplakia and dysplasia.

A hard tissue capable CO₂ laser has become available recently. This laser’s CO₂ molecule uses an oxygen isotope that creates a beam at 9300 nm. This particular wavelength has a high absorption affinity for hydroxyapatite that allows for efficient vaporization of tooth structure. Its water absorption is much lower than Erbium lasers so hydroxyapatite absorption and vaporization predominates when cutting enamel, dentin, and bone. Hard tissue ablation with the 9300 nm CO₂ laser is a photothermal event, not photoacoustic. As a result much higher temperatures are generated and much higher pulse rates are needed to cut.

**Laser Safety**

Proper safety procedures must be put in place by any practice implementing laser use. A laser safety officer needs to be appointed by the clinic whose job it is to implement and monitor safety protocols. The manufacturer of each device is obliged to train the providers the important safeguards needed for each device.

Common safety practices include:

- **Eye Protection** – The patient, clinical staff and any observers must wear protective eyewear specific for the wavelength being used.
- **Plume Control** – Laser procedures create a plume that may contain hazardous chemicals and microflora. Standard dental high-speed evacuation properly used is adequate to control the plume. Good quality masks need to be worn by the clinicians.
• **Sharps** – Scored laser tips of quartz fibers are considered sharps and need to be disposed of as such.
• **Warning Sign** – Warning signs need to be in a visible place and access to the operatory limited.

**Laser Procedures**
There is not a discipline in dentistry where lasers are not helpful. Examples in each discipline will be presented including the following:
• Laser assisted caries diagnosis and management
• Restorative dentistry
• Surgical applications of dental lasers
• Oral diagnosis/oral medicine
• Oral surgery
• Periodontics – gingivectomy, crown lengthening, periodontitis treatment
• Pediatric – restorative, frenectomy
• Endodontics
• Biostimulation

**Laser Assisted Caries Diagnosis and Management**
The Diagnodent caries detection laser is a portable, battery powered diode laser. Its 655 nm visible wavelength causes active caries to fluoresce. The amount of fluorescence is measurable and is correlated to the size and direction of the lesion. When combined with Caries Management by Risk Assessment (CAMBRA) it can be a very useful tool for detecting and managing early caries. The laser gives a reading of zero to 99. A general guideline is that occlusal lesions above 30 likely need restoration and those from ten to 30 are potentially reversible. The Diagnodent can be an excellent tool for measuring the effectiveness of non-surgical interventions such as increased fluoride exposure, dietary changes, and the like. It also is excellent at detecting “hidden caries” in pits and fissures. Occlusal lesions in a fluoridated population can often be quite advanced before cavitation can be detected with an explorer. Laser diagnosis can help solve this vexing problem for the modern dentist when aired with CAMBRA and high magnification visualization.

The Diagnodent's primary indication is for detecting class I, class V, and incisal caries. It can also be useful when paired with transillumination for detecting permanent

---

**Figure 8. Diagnodent.** Diagnodent caries diagnostic device. Active caries is fluoresces when exposed to 655 nm visible laser light. The amount of fluorescence is measurable and is correlated with the size of the lesion.
class III and primary class 2 lesions. Experienced clinicians have found they can greatly reduce the need for radiographs to detect these particular lesions. Laser caries detection can also be used intraoperatively to check minimally restorative preparations for complete decay removal.

The Diagnodent’s primary indication is for detecting class I, class V, and incisal caries. It can also be useful when paired with transillumination for detecting permanent class III and primary class 2 lesions. Experienced clinicians have found they can greatly reduce the need for radiographs to detect these particular lesions. Laser caries detection can also be used intraoperatively to check minimally restorative preparations for complete decay removal.

Restorative Dentistry
Er:YAG and Er,Cr:YSGG machines are multi tissue lasers that are FDA approved for cutting tooth, bone and soft tissue. Their extremely short pulses and high peak power allow for efficient enamel and dentin photoacoustic ablation. Erbium lasers can prepare all classes of restorations. Many restorations can be accomplished without local anesthesia. Experienced laser practitioners report needing anesthesia only ten to 20% of the time, usually for amalgam removal, very large lesions, or particularly sensitive teeth.

Advantages of using erbium laser for operative dentistry include:
- Precise ablation allows for minimally invasive preparations
- Smear layer removal
- Disinfection of preparations
- Eliminates the noise, heat, and vibration of high speed rotary instrumentation
- Reduced need for local anesthesia
- Selective caries removal due to carious dentin’s higher water content and softer consistency

Surgical Applications of Dental Lasers
All four major wavelengths of dental lasers can be used as soft tissue surgical devices. The primary chromophores for diode and Nd:YAG lasers are pigments such as hemoglobin and melanin. Diode lasers when used surgically use the indirect heat generated by the pigment initiated on to the fiber tip. The erbium and CO₂ lasers are mostly absorbed by water. All these lasers use photothermal effects to incise tissue whereby photons absorbed are converted to heat energy in order to do work. Diode and Nd:YAG lasers exhibit much deeper tissue penetration and thermal effects than the erbium lasers and the potential for tissue damage is greater. As such, proper training and an understanding of the biological effects of lasers are imperative for any provider wanting to pursue laser dentistry.

Thermal relaxation varies depending on the laser and parameters employed. Erbium lasers exhibit the greatest thermal relaxation due to their short free running pulses, low hertz, and minimal tissue penetration. Histological examination of erbium incised tissue exhibits almost no tissue damage or inflammatory response. Nd:YAG lasers also run on free running pulsed mode with pulse durations as short as 100 microseconds. However, due to their high absorption by pigment and deeper penetration they exhibit significantly greater heating of tissue and this factor needs to be respected by the practitioner. Diodes and CO₂ lasers run in continuous or gated wave mode so they have much less thermal relaxation capabilities. Recent technological advances in
Figure 9a. Class I Composite.

1. No discernible explorer stick but Diagnodent indicated caries in distal fissure, mesiolingual cusp, and some early decay under the sealant in the mesial pit.
2. Some remaining decay revealed by caries indicator in distal fissure after initial Er:YAG laser preparation.
3. Final preparation; no anesthesia was used.
4. Final restoration, the mesial sealant was removed with the laser and resealed.

so called “superpulsed modes” have helped improve the thermal parameters of these lasers, but it is important to note this is not a true free running pulsed mode.

Er:YAG and Er,Cr:YSGG lasers are also capable of cutting bone and have FDA clearance for osseous use. Multiple studies have shown erbium irradiated bone shows minimal thermal damage, necrosis, or inflammation. Clinically this relatively atraumatic cutting of bone results in rapid and comfortable healing observed by laser practitioners. Studies have shown bone cutting with Er:YAG laser to be superior to bur cuts. Er:YAG ablated bone shows no smear layer and no necrotic osteocytes adjacent to the cut. Erbium lasers have been shown to effectively decontaminate implant surface without damaging titanium and are useful in treating peri-implantitis.

Periodontal Pocket Therapy
All four major dental laser wavelengths have been used for the treatment of periodontal disease. Diodes, Er:YAG, Nd:YAG, and CO₂ devices from various manufacturers have received FDA clearance for sulcular debridement, defined as removal of diseased or inflamed soft tissue in the periodontal pocket to improve clinical indices including gingival index, gingival bleeding index, probe depth, attachment level and tooth mobility. In 2004 Millennium Dental received FDA clearance for the Nd:YAG LANAP® Procedure (Laser Assisted New Attachment Procedure – cementum-mediated new periodontal ligament attachment to the root surface in the absence of long junctional epithelium). Nd:YAG and erbium lasers have been the most studied and utilized wavelengths in periodontal therapy. Nd:YAG lasers are useful in periodontal care because of their affinity for pigment allows for selective debridement of diseased sulcular epithelium. The Nd:YAG wavelength is also bactericidal, biostimulative, and has the ability to stimulate fibrin formation with the proper parameters. Erbium lasers have been shown to be effective at scaling and root planning.
Effective pocket decontamination, and can replace scalpels when incisions are needed. One notable advantage to laser techniques is a predictably more comfortable post-operative experience for patients.

**Laser Biopsy**
All dental laser wavelengths are capable of performing precise biopsies. Smaller lesions can often be removed with a compounded topical anesthetic only. Sutures are rarely needed due to the excellent hemostasis and minimal trauma observed when lasers are used properly. Any lesion removed needs to be submitted to an oral pathologist for microscopic diagnosis. The dentist should also note what type of laser was used as there is often a tissue effect visible along the incision known as a “laser artifact.” The artifact varies depending on the thermal effects of the particular laser and settings used.

**Gingivectomy**
Gingivectomy is the most common procedure performed with dental lasers. All laser wavelengths can be used to precisely incise gingiva for restorative, cosmetic, and periodontal indications. Rapid healing and reduced pain are commonly seen post-operatively and patients rarely need periodontal packing or sutures. The thermal effects of diodes, Nd:YAG and CO$_2$ lasers must be understood to avoid collateral damage, but in properly trained hands these devices are quite effective. Erbium edlasers pulsed technology, shallow penetration, and water absorption produce a minimal thermal effect and minor procedures can sometimes be achieved with no anesthetic at all. The nearly “cold cutting” effect of erbium tissue interaction creates a remarkable post-operative course.

**Frenectomy**
Frenectomies are a very common laser procedure that can be accomplished effectively with any wavelength. Simple ones can often be achieved with topical anesthesia only. Hemostasis is usually excellent, particularly with the more thermal CO$_2$, Nd:YAG, and diodes.

---

**Figure 18.** Oral Diagnosis - Fibroma removal.
Er:YAG laser excisional biopsy of a fibroma on the buccal mucosa. A compounded topical anesthetic was used. No sutures were placed and the patient had a comfortable postoperative course. The picture on the right is at six months follow-up exhibits healing with no scarring.
Figure 19. Crowns/Gingivectomy.
Pre-operative severe idiopathic gingival hyperplasia. The anterior teeth were highly restored with multiple restorations and resin veneers. Crowns were indicated and the patient's chief complaint was that her teeth looked too short, even though the prior veneers established an incisal position many millimeters below the occlusal plane.

Figure 20. Crowns/Gingivectomy.
Immediate post Er,Cr:YSGG gingivectomy and gingivoplasty just prior to crown preparation at the same appointment. No osseous reduction was needed, as there was no biological width disruption.
Figure 21. Crowns/Gingivectomy - One week later. Teeth were temporized with a chair-side fabricated six unit splint and the patient returned for impressions one week later. The patient complained of minor discomfort only. The gingiva already appears well healed with stippling apparent just one week later.

Figure 22. Crowns/Gingivectomy - Cementation. Gingivectomy and Class V Restoration - An elderly patient lost a class V restoration while hospitalized. The gingiva grew into the defect significantly. The patient was on Plavix and aspirin. Er:YAG gingivectomy allowed for precise control of the gingival margin and placement of a restoration.
Figure 23. Implant/Gingivectomy.
Fibrous gingiva growing over implant healing cap excised with Er:YAG laser at abutment placement appointment. No anesthesia was required. Erbium lasers do not interact with titanium and can be safely used around titanium implants.

Video 2. Gingivectomy with a diode laser (1064 nm XLASE).

Figure 24. Frenectomy. Frenum contributing to recession between teeth 24 and 25.

Figure 25. Frenectomy. Immediate post-operative view of Er:YAG frenectomy. Topical anesthesia was used. The frenum is incised and the gingival tissue is obliterated with the laser to help prevent relapse and encourage growth of attached gingiva.
**Flapless Crown Lengthening**

**Figure 26.** Frenectomy - Six Months Post-op. Six months post-operative view of an Er:YAG frenectomy. Attached gingiva has grown into superior portion of the surgical site.

**Figure 27.** Crown Prep/Crown Lengthening. Fractured buccal cusp on 70-year-old female requires osseous crown lengthening due to biologic width impingement on mesial and buccal.
Figure 28. Crown Prep/Crown Lengthening. The hard tissue crown lengthening can be done with a flapless approach if two millimeters or less of bone needs to be removed. Enough bone has been removed with the Er:YAG laser to assure adequate distance from the final crown margin and osseous crest for biological width requirements.

Figure 29. Crown Prep/Crown Lengthening. The tooth is built up with a high contrast composite material and prepared for the crown on the same appointment as the crown lengthening.
Figure 30. Crown Prep/Crown Lengthening. A final impression is taken that day as well.

Figure 31. Crown Prep/Crown Lengthening - Two Weeks Later. The sulcular and attached gingiva are healing well at the crown delivery appointment two weeks after osseous crown lengthening. The patient reported no significant pain post-operatively.
**Crown Lengthening with Minimally Invasive Flap Design**

*Figure 32.* Crown Prep/Crown Lengthening. The crown is delivered two weeks after the osseous crown lengthening.

*Figure 33.* Build-up/Crown lengthening. Mesiolingual cusp fracture requires osseous crown lengthening. The fracture was subgingival to the level of the bone. A flap is required due to significant amount of bone needed to be removed and the width of the bone in this region.
Figure 34. Build-up/Crown lengthening. A conservative flap is laid using the Er:YAG laser in place of a scalpel. The bone is removed to the proper height and contoured. A band is placed and high contrast composite buildup bonded in place. A single nylon suture secures the minimally invasive flap. The final crown preparation can be done in two to four weeks.

Figure 35. Build-up/Crown lengthening. The permanent crown is delivered four weeks after the crown lengthening procedure. The margin is three millimeters from the osseous crest and adequate ferule established.
**Oral Surgery**

CO₂ lasers have been popular in oral surgery due to their precise incisions and excellent hemostasis. Erbium lasers are capable of cutting bone in a less traumatic fashion and can be quite useful for the following procedures:

- Surgical Extractions with less traumatic flaps and bone removal
- Alveoplasty
- Incision and Drainage
- Operculectomies
- Treatment of peri-implantitis
- Pre-Prosthetic
  - Ridge preparation/hyperplastic tissue reduction
  - Frenectomies
  - Tuberosity reductions
  - Vestibuloplasty
  - Tori Removal

Nd:YAG and diodes have biostimulative properties that can be used to promote healing, osteogenesis, and post-operative comfort.\(^\text{16}\) Nd:YAG lasers can also form fibrin rapidly in an extraction site creating a quick and more durable clot. An interesting application of dental lasers is in the treatment of bisphosphonate induced osteonecrosis of the jaw (BONJ). BONJ occurs because the drugs inhibit osteoclastic activity which is needed whenever bone is surgically manipulated. When the necrotic bone is removed with an Er:YAG laser the remaining bone is so minimally traumatized that osteoclastic needs are minimized. Nd:YAG biostimulation can be used concurrently or separately to promote bone healing as well. Recent studies have shown superior results when compared to traditional surgical approaches when lasers are used.\(^\text{11,14,15,17}\)

**Lasers in Pediatric Dentistry**

Dental lasers offer many advantages when treating children.\(^\text{16}\) All procedures previously discussed apply to pediatric treatments as

---

**Figure 36. Oral Surgery.**

A 79-year-old female fractured off a crown on tooth number 9 in a car accident. The Er:YAG is used in a flapless approach to resect bone and make space in the periodontal ligament for judicious elevation. No sutures were needed.
affinity for water of the Er:YAG laser creates an interesting phenomenon when specially shaped radial firing tips are placed in irrigant solutions. When these special tips are submerged in solution each pulse sends a powerful wave of acoustic energy throughout the solution. The laser is used at a setting that creates very little thermal effect. The resultant shock wave propagates throughout the complete three-dimensional root canal system, even the tiniest accessory canals. Scanning electron microscope and microbiological studies have shown extremely thorough cleansing and disinfection of the total root canal complex.\textsuperscript{18,19} The PIPS technique allows the dentist to instrument less aggressively and still achieves a thoroughly clean root canal system.

A modified PIPS technique called SWEEPS (Shock Wave Enhanced Emission Photoacoustic Streaming) has been recently developed. This technique uses a second variably timed pulse to enhance the shockwave of PIPS by about 30 percent.

Endodontic Applications
Nd:YAG, Erbium Lasers and diodes have been studied extensively as an adjunct to endodontic treatment. Many of these studies have shown improved smear layer removal and disinfection in the apical third of the tooth. There is the concern of negative thermal effects within the confined space of the root canal.

Recently a phenomenon known as PIPS (Photon Induced Photoacoustic Streaming) has been discovered. The extremely high peak power and affinity for water of the Er:YAG laser creates an interesting phenomenon when specially shaped radial firing tips are placed in irrigant solutions. When these special tips are submerged in solution each pulse sends a powerful wave of acoustic energy throughout the solution. The laser is used at a setting that creates very little thermal effect. The resultant shock wave propagates throughout the complete three-dimensional root canal system, even the tiniest accessory canals. Scanning electron microscope and microbiological studies have shown extremely thorough cleansing and disinfection of the total root canal complex.\textsuperscript{18,19} The PIPS technique allows the dentist to instrument less aggressively and still achieves a thoroughly clean root canal system.

A modified PIPS technique called SWEEPS (Shock Wave Enhanced Emission Photoacoustic Streaming) has been recently developed. This technique uses a second variably timed pulse to enhance the shockwave of PIPS by about 30 percent.
Figure 38. Restorative. Class II caries in teeth A and B in a 7-year-old male.

Figure 39. Restorative.
1. Lesions were prepared with Er:YAG laser without anesthesia. No high speed handpiece was used. Some caries was excavated at 5000 RPM using a ceramic round bur that selectively removes carious dentin only (CeraBur by Komet)
2. Teeth were restored with Glass Ionomer restoration.
Figure 40. Frenectomy. Four-year-old male with significant ankyloglossia and having some speech problems.

Figure 41. Frenectomy. Immediate postoperative appearance. Topical anesthesia was used and immediate release of the frenum was achieved.
Figure 42. Frenectomy – Six months post-op. Six months follow up and no relapse of the ankyloglossia is present. His speech problem resolved quickly with speech therapy after the surgery.

Video 3. Topical anesthetic is applied and a canine is exposed with a diode laser (1064 nm XLASE). Procedure done by Dr. Larry Kotlow, video courtesy of Technology4Medicine, LLC. Click on image to view video online.
Figure 43. Endodontics.
Tooth 5 instrumented to a size 25 hand file and treated with the PIPS (Photon Induced Photoacoustic Streaming) using sodium hypochlorite, sterile water and EDTA. EndoRez cement (Ultradent Products) was used with a single gutta percha cone per canal. There are multiple lateral canals filled with cement both mid root and apically.

Figure 44. Photon Induced Photoacoustic Streaming (PIPS).
This molar was treated with PIPS only with no mechanical instrumentation and then sealed with EndoRez to demonstrate the effectiveness of the procedure. Multiple lateral canals were cleaned and sealed effectively.

Figure 45. Laser treated canal. Normal instrumentation and irrigation leaves significant smear layer on the left. The PIPS treated dentin on the right is free of smear layer. Photo courtesy of Dr. Enrico DiVito.

Figure 46. Treated Lateral Canal. A lateral canal in a PIPS treated tooth is free of debris. Photo courtesy of Dr. Enrico DiVito.
Photobiomodulation (Biostimulation)
All four laser types discussed here have photobiomodulation properties in addition to their surgical capabilities. The terms Low Level Laser Therapy (LLLT) or biostimulation are often used to describe this phenomenon.

In dentistry biostimulation can be used for many things including:
• Treatment of recurrent aphthous stomatitis and traumatic ulcers.
• Reduction of oral edema.
• Post-operative analgesia following periodontic, oral surgery, and endodontic procedures.
• Treatment of recurrent intraoral and labial herpes.

• Management of inflammatory conditions such as erosive lichen planus.
• Reduce pain of orthodontics.
• Management of temporomandibular disorder.

Conclusion
Dental lasers are now well established instruments. Ongoing research is showing the many benefits of laser therapy. The ability to perform less invasive procedures with greater patient comfort makes laser dentistry something the modern practitioner should consider. A thorough understanding of laser physics and biological effects is mandatory for any provider. Comprehensive beginner and ongoing training is imperative to use these devices effectively and safely.
Figure 47. Laser treatment of Aphthous Ulcers.
Recurrent aphthous stomatitis treated with combination therapy of Nd:YAG and Er:YAG biostimulation. The patient feels immediate pain relief and the lesion usually remains comfortable. This particular patient's aphthous ulcers usually last ten to fourteen days yet with laser treatment the ulcer heals in a matter of days.

Figure 48. Oral Diagnosis – Herpes Treatment.
This patient suffered from recurrent palatal herpes type I outbreaks two or three times a year. The lesion had just started when treated with dual wavelength biostimulative therapy with an Nd:YAG and Er:YAG laser. Her relief was immediate and at two day follow up the lesion had already repithelialized fifty percent.

To receive Continuing Education credit for this course, you must complete the online test. Please go to: www.dentalcare.com/en-us/professional-education/ce-courses/ce394/start-test

1. **The first laser ever built in 1960 was _________.**
   A. CO$_2$
   B. erbium
   C. Nd:YAG
   D. ruby

2. **The first laser marketed to dentistry was _________.**
   A. Er:YAG in 1995
   B. Nd:YAG in 1990
   C. Nd:YAG in 1987
   D. A diode in 1991

3. **Laser is an acronym for _________.**
   A. light amplitude by simple emission of radiation
   B. level amplified stimulated emission of radiation
   C. light amplification by stimulated emission of radiation
   D. lowered amplification of static emitted radiation

4. **Dental laser beams are _________.**
   A. monochromatic, non-coherent, and multidirectional
   B. ionizing, monochromatic, and unidirectional
   C. monochromatic, coherent, and unidirectional
   D. non-ionizing, monochromatic, and emitted from a passive medium

5. **Optical Pumping is used to achieve which step in laser creation?**
   A. Amplification
   B. Emission
   C. Radiation
   D. Stimulation

6. **Laser power is _________.**
   A. the rate of energy used and is measured in watts
   B. the amount of energy produced and is measured in millijoules
   C. the product of pulses per second and wattage
   D. greatest in diode lasers

7. **The emission mode that has true pulsed bursts of laser energy is _________.**
   A. continuous
   B. free running pulsed
   C. gated wave
   D. intermittent

8. **A laser running in continuous mode’s peak power is _________.**
   A. higher than its average power
   B. lower than its average power
   C. the same as its average power
   D. why it is so useful for cutting enamel and dentin
9. **Thermal relaxation refers to** ____________.
   A. the ability of biostimulation with lasers to relax skeletal muscle  
   B. the ability of biostimulation to dilate capillaries and increase blood flow  
   C. the ability of the active medium crystal to cool itself in free running pulsed mode  
   D. the tissue's ability to absorb and dissipate heat to help minimize thermal damage with pulsed laser usage

10. **The actual physical work done by a laser is mostly a result of which interaction?**
    A. Scattering  
    B. Absorption  
    C. Transmission  
    D. Refraction

11. **Which of the following statements are true?**
    A. Erbium lasers primary chromophore is water and Nd:YAG lasers primary chromophores are pigments like hemoglobin or melanin.  
    B. CO₂ lasers are primarily absorbed by water.  
    C. Shorter near infrared laser wavelengths of diodes and Nd:YAG exhibit greater tissue penetration than erbium lasers.  
    D. All of the above.

12. **Fluorescence of tissue stimulated by laser light is mostly important in** ____________.
    A. caries diagnosis  
    B. biostimulation  
    C. periodontal therapies  
    D. A and B

13. **The primary biological effect of lasers when performing soft tissue procedures is** ____________.
    A. photochemical  
    B. photoacoustic  
    C. photothermal  
    D. photodisruptive

14. **When tissue is heated to 60 degrees C,** ____________.
    A. protein will begin to denature  
    B. tissue is vaporized  
    C. tissue will show signs of carbonization  
    D. None of the above.

15. **Erbium lasers** ____________.
    A. all have identical wavelengths  
    B. all exhibit identical water absorption  
    C. are hard and soft tissue capable  
    D. run in continuous emission mode

16. **When cutting hard tissue with an erbium laser,** ____________.
    A. longer pulse durations are preferable  
    B. minimal thermal effects are observed in adjacent tissue when used properly  
    C. shorter pulse durations have lower peak power  
    D. anesthesia is always needed when preparing teeth
17. Nd:YAG lasers
A. are available in multiple wavelengths
B. use primarily photoacoustic effects to work
C. are 1064 nm wavelength
D. exhibit minimal tissue penetration

18. Fibrin formation with an Nd:YAG laser
A. is maximized at a 650 microsecond pulse duration
B. can be utilized after an extraction to help form a clot in the socket
C. is useful when treating periodontal pockets
D. All of the above.

19. Diode lasers
A. are the most expensive of all types of dental lasers
B. are available in only a single wavelength
C. use a semiconductor stimulated by electricity to produce laser light
D. have hard tissue capabilities

20. Water is the primary chromophore for diode laser wavelengths. Diode lasers run in free running pulsed mode.
A. Both statements are true.
B. The first statement is true and the second statement is false.
C. The first statement is false and the second statement is true.
D. Both statements are false.

21. CO₂ Lasers
A. are the most recently developed of the dental lasers
B. do not use quartz optical fibers as their beam transfer hardware
C. have extensive hard tissue capabilities
D. are efficient at cutting tissue but exhibit poor hemostasis

22. When using dental lasers
A. safety glasses made specifically for the wavelength must be worn by all patients, staff, and observers
B. universal laser safety glasses can be used
C. only the patient needs to wear eye protection
D. no eye protection is needed when using an Nd:YAG laser

23. The laser plume
A. may contain hazardous chemicals and infectious agents
B. necessitates the need for high speed evacuation
C. is a reason for staff to wear high quality masks
D. All of the above.

24. The Diagnodent diagnostic laser
A. can only be used to diagnose class I caries
B. is 655 nm visible light
C. indicates all positive readings need to be restored
D. is not used on pediatric patients
25. When performing operative dentistry with erbium lasers enamel is removed via __________.
   A. vaporization
   B. carbonization
   C. photoacoustic ablation
   D. very long pulse durations

26. Experienced erbium laser users usually __________.
   A. do not need local anesthesia for the majority of restorations
   B. routinely remove amalgam with their lasers
   C. only use their laser for class I and V lesions
   D. anesthetize approximately half of the time

27. When considering soft tissue uses of lasers, __________.
   A. only diodes, Nd:YAG, and CO₂ lasers can be used
   B. the practitioner does not need to understand the differing thermal and biological effects of differing wavelengths as all soft tissue lasers behave similarly
   C. thermal relaxation does not matter as it only occurs when cutting hard tissue
   D. None of the above.

28. For cutting bone, __________.
   A. any wavelength can be used, though they differ in their effectiveness
   B. Er:YAG and Er,Cr:YSGG lasers have FDA clearance
   C. erbium lasers cause much more damage to bone than surgical burs
   D. narcotic analgesics are usually needed post-operatively when lasers are used

29. When submitting a laser resected biopsy, __________.
   A. no special instructions are needed
   B. only lesions suspected of being dysplastic or malignant need to be examined microscopically
   C. the dentist should indicate on the lab form that a laser was used and what type of laser
   D. all lasers leave identical artifacts on the specimen

30. P.I.P.S. stands for __________.
   A. Photon Induced Plasma Streaming
   B. Photon Induced Photoacoustic Streaming
   C. Plasma Inverted Photonic Stimulation
   D. Photon Inversion by Plasma Stimulation
